Evaporation and Distillation

Add the correct punctuation to the following paragraphs:

Evaporation is the process in which heat causes a liquid to change into a gas. This leaves behind any solutes that were dissolved in the liquid. Salt is a solute in sea water, and is left behind after the water evaporates.

Evaporation is a natural process that dries up pools of water on the road and clothes on a line. Evaporation is also used in the laboratory to separate a solvent from its solute. However, the solvent is lost to the atmosphere. This means that you only collect the solute. The solute often forms crystals in a process called crystallisation.

Evaporation is the process in which a liquid turns into a gas. Condensation is the opposite: a gas cools to form a liquid. Distillation uses both evaporation and condensation to separate substances.

Evaporation loses the liquid solvent to the atmosphere, but sometimes you need to keep the liquid as well. In distillation, the gas is condensed back into a liquid so that it can be collected. If the solvent is water, distillation first evaporates off the water. It then cools the water vapour so that it condenses back into liquid water. The apparatus that converts the gas back to the liquid is called the condenser.
